Declinatio

THE 5-25 GHz High-resolution radio continuum SNRs images at frequencies above 5-10 GHz are surprisingly lacking. Our observations with the Sardina Radio Telescope (SRT) shed new light on spectral features and breaks up to 25 GHz. Synchrotron cutoff differences between different SNR complexes could be related to still poorly understood different primary and secondary (from hadron interactions) electron energy distributions and/or magnetic fields, accordingly to local shock conditions arising from different interacting structures in the ISM. We are providing spectro-polarimetric

Left: SRT continuum map of Tycho SNR at 21.4 GHz. Right: Spectral energy distribution for a

imaging in the frequency range 5-25 GHz of a selected SNRs sample: W44, IC443, Cygnus Loop, Kes 73, G85.4+0.7. Our aim is to disentangle magnetic processes from spectral variation contributions due to different primary and secondary electron populations.

circle: TeV gamma-ray emission (Albert et al. 2007). Green region: bulk of the radio emission.

Spectral energy distribution from 0.408 to 857 GHz. Filled red diamonds: SRT measurements (Egron et al., 2017; Loru et al., 2019). The solid line model includes both synchrotron and spinning dust emission components (Onić et al., 2017).

• Assuming a magnetic field in the range 18–90 μ G, our result on W44 provides a direct estimate for the maximum energy of accelerated cosmic ray electrons in the 6-13 GeV range, which is consistent with evidence from gamma-ray observations (Ackermann et al., 2013). Assuming instead a locally enhanced magnetic field of $\sim 1 \text{ mG}$ (Cardillo et al. 2016), the corresponding maximum electron energy would be < 2 GeV (secondary electrons?). • Our flux density measurement at 21.4 GHz independently supports the claimed spectral bump in IC443 (spinning dust process; Onić et al., 2017). A correlation between the TeV emission and radio bright/flat-spectrum regions could be related to an increase in hadron emission and a significant secondary electrons injection. • High-frequency polarimetric images represent a major challenge in order to better constrain the magnetic field (regular or enhanced?) • See Egron, Pellizzoni, Iacolina et al., MNRAS, 470, 1329, 2017 and Loru, Pellizzoni, Egron et al., MNRAS, 482, 3857, 2019

We collected single-dish images of SNR+PWN Kes 73 at frequencies >6 GHz and coupled them with lower frequency interferometric images (Ingallinera et al., 2014). No spectral changes are evident in the total flux density, but strong region-dependent spectral variations are observed.
